Oak growth in Midwestern North America linked with post glacial climate epochs in the North Atlantic

Early Holocene tree-ring climate proxy development from sub-fossil oak wood (buried wood not mineralized) has been limited to Europe. Sub-fossil oak that has been collected from the rivers of Missouri and Iowa is abundant, well preserved, and has been determined to be at least 13.82 cal ka BP in age. This ancient oak wood represents riparian forest trees (Quercus bicolor Mich. and Quercus macrocarpa Mich.) that have been recruited into sediments by flooding and the erosion of stream banks. Large and heavy oak trees become buried rapidly by stream sediments and are then stored in the broad floodplains of these low-gradient streams for thousands of years. Although recruitment, reburial, excavation, and movement of wood is common, the relatively short length of these streams ensures that sampled oak is rarely, if ever, more than 50 km from where it originally grew, thus, spatially defining the climate region of origin. About 7 ancient oak trees (>500 yrs BP) are found per km of stream reach that have a sufficient number of rings (90 to over 280) for use in the construction of tree-ring chronologies. The 14C and tree-ring dating of the 230 oak trees collected to date indicate that the average tree grew about 2000 years ago.

One of several ongoing projects utilizing ancient oak wood is the documentation of growth and climate during the last post glacial climate epoch, in what is now part of the mid-continental North American agricultural region. One of our goals is to link well-documented climate change in maritime environments with the continental climate of what are now important agricultural regions. For example, the Younger Dryas event has been documented in the North Atlantic and Europe as a period of time marked by abrupt climate change and cooling (Alley, 2000). Here, we provide tree-ring and isotopic evidence that growth and climate change were synchronous between the North Atlantic and mid-continental North American sites that lie 12,000 km to the southwest.

Oaks that were dated between 9.5 and 14 cal ka BP using 14C and density dating (Guyette and Stambaugh, 2003) showed decreased growth (Fig. 1) and depleted δ13C (Fig. 2) coincident with North Atlantic climate proxies. The mean annual basal area increment (BAI; an area-based metric of tree stems) of oak trees was significantly (p <0.01) less (6.5 cm2/yr) during the Younger Dryas (Fig. 1) compared to growth during the rest of the post glacial climate period (11.2 cm2/yr). Mean maximum annual BAI (17.0 cm2/yr) was reduced by 54% during the Younger Dryas. Between-tree growth variance in BAI was about 75% less during the Younger Dryas than during the whole post glacial period (9.5–11.5 and 13–14 cal ka BP). A decrease in the variance of growth rates within a tree population would be expected if limits on growth switched from highly variable endogenous factors (forest competition) to regional exogenous factors (climate). Five-point moving averages of the mean ring width of the oak trees and temporally paired δ18O values (Fig. 2) from Greenland ice (GISP2) were correlated (r = 0.57) during the post glacial climate period. Whole tree mean ring width was significantly (p <0.01) reduced during the Younger Dryas compared to adjacent post glacial climates. In addition to growth evidence, the low abundance of oaks in the early part of the Younger Dryas suggests a climate that was limiting to oak reproduction. The longest temporal gap between sample dates in the 14,000-year-record occurs during the first part of the Younger Dryas ca. 12.48 to 12.99 cal ka BP, and coincides with gaps in the European record (Friedrich et al., 2004). This suggests unfavorable conditions may have existed for regeneration and growth of trees across both continents during the first half of the Younger Dryas.

Values of δ13C (Fig. 2) in oak wood are found to be positively and significantly correlated (r = 0.74)
Consolidating high- and low-resolution information from different sources into a Northern Hemisphere climate reconstruction

Our understanding of climate history in the pre-industrial era relies principally on climate proxies, each of which has strengths and limitations in representing past climate variability. A paleoclimate reconstruction from borehole temperature data has its foundation in the theory of thermal diffusion and, as such, is characterized by a progressive inability to resolve climatic excursions in the more remote past. But the compensation for the loss of resolution is a better determination of the mean surface temperature in the interval of time for which the details cannot be resolved. Conversely, reconstructions from many traditional proxy approaches offer higher temporal resolution of relative changes but with greater uncertainties in the long-term trends.

It would be desirable to develop a technique to integrate complementary high- and low-resolution climate information preserved in different data sources for a more complete picture of the past climate change. Huang (2004) attempted such an integrated reconstruction of the Northern Hemisphere surface temperature history over the past five centuries through an integrated analysis of the global da-
